Abstract

A criterion of local continuity of the relative entropy of resource — the relative entropy distance to the set of free states — is obtained. Several basic corollaries of this criterion are presented. Applications to the relative entropy of entanglement in multipartite quantum systems are considered. It is shown, in particular, that local continuity of any relative entropy of multipartite entanglement follows from local continuity of the quantum mutual information.

1 Introduction and preliminaries

In recent years, the mathematical framework of quantum resource theories has emerged as a unifying paradigm to investigate the transformation of quantum resources [1]. In this framework, quantum states can be either 'free', meaning that they can be prepared relatively inexpensively with the equipment and operational constraints at hand, or 'resourceful', meaning that they are difficult to obtain and therefore potentially exhibit some useful property that free states do not. One of the central problem in quantum resource theories is resource quantification: how to quantify the resource content of states that are not free? Among the several resource measures available, the relative entropy of resource [2, 3, 4], defined as the distance from the set of free states measured by the quantum relative entropy [5, 6], has been identified as a key universal resource quantifier. In the paradigmatic case of entanglement theory, from whose blueprint the framework of quantum resource theories developed, this is nothing but the relative entropy of entanglement that has been the subject of much investigation [2, 7, 8, 9, 10, 11, 12, 13, 3, 4]. More generally, the importance of the relative entropy of resource stems from the fact that its regularised version is believed to represent both the ultimate rate of conversion between different states under the constraints of the given resource theory, and the Stein exponent associated with hypothesis testing of
