Abstract

Quantum walks on graphs are fundamental to quantum computing and have led to many interesting open problems in algebraic graph theory. This review article highlights three key classes of open problems in this domain; perfect state transfer, instantaneous uniform mixing, and average mixing matrices. In highlighting these open problems, our aim is to stimulate further research and exploration in this rapidly evolving field.

1 Introduction

Quantum walks on graphs are essential for quantum computing. Amongst other important advances, quantum walks were shown to be a universal computational primitive in a landmark result of Childs in [8]. They have also gained prominence in algebraic graph theory; many problems arising in the study of quantum walks have given rise to interesting combinatorial problems. There are many open problems in this rapidly evolving field, and in this review article, we highlight three classes of problems, place them in context with relevant results and propose several unsolved problems.

Most of the results stated in this text are either not new or follow easily from known facts, but there are some new theorems. These are not the focus of this paper; our main goal is to survey the basics and propose problems we believe are central to the field. We refer the reader to [15] for a full survey of the basic result. For the purposes of this paper, we give a very brief introduction, as follows.

The *transition matrix* of a *continuous-time quantum walk* on a graph G with adjacency matrix A is a matrix-valued function in time, denoted $U(t)$, and is given as follows:

$$U(t) = \exp(\mathrm{i}tA).$$
